Online Smart Sensor to Measure Stockpiles used in Mineral Processing

Xiaowei Pan

Abstract—With the advancement and the wide usage of measurement instruments associated with stockpiles, such as weightometers, a smart sensor can be developed to online monitor the level of a stockpile. Furthermore, the stockpile smart sensor can be used to determine the mixing behaviour of different ores discharged out of the stockpile, by combining the smart sensor technique and finite element modelling. The mixing behaviour of different materials includes when and how the mixing takes place, and more important, when the mixed materials with a certain portion is discharged out of the stockpile. In this article, only the level function of the stockpile smart sensor will be discussed in detail.

The stockpile smart sensor can help estimate accurate residual time for different group of ores charged to the stockpile. The smart sensor makes it possible to monitor the behaviour of different ore types in real time in a stockpile, including when and how the different ores are mixed in the stockpile and when the mixed ores are discharged with certain mixing portion. Using the smart sensor system, the information on ore types can be provided for ores that are discharged from the stockpile. The ore type information includes ore grade, density, hardness, strength, etc. The stockpile smart sensor, developed originally for a diamond mine, can be used for stockpiles of other mines, including iron ore mines, coal mines, copper mines, chromium ore mine, and cement plants.

Keywords—Stockpile measurement, Smart sensor, Soft sensor

I. CHALLENGES OF STOCKPILE MEASURES

A LOT of efforts have been made in the development of level measurement for stockpiles, used commonly in mining/mineral processing and cement industries. Stockpiles, see in Figure 1[1], are used as an intermediate buffers between inventory and production. Their sizes vary according with the scales of production, typically above 10 m in height. Issues, such as safety, reliability and accuracy, remain crucial, and meanwhile the level measurement technologies need to be easy to install and operate, at a low cost of ownership.

Fig. 1 The Illustration of a stockpile ideally used in mining, mineral processing and cement production

The techniques for measuring stockpile levels range from basic devices to the high technological systems. Before instrument based measurement became widely used, stockpile levels were often determined by mechanical means. One such technique, such as Yo-Yo or plumb Bob [2], required the lowering of a measuring rope attached to a weight from the stockpile top, showing the distance to the surface by how much rope was used. Such measurement is categorised as contact level measurement. When level measurement requires more precision, instruments, based on high technologies, are widely used, including ultrasonic, radar and laser [3].

It is difficult to measure the stockpile level using those measurements as mentioned above, when its shape and location are not in a fixed pattern. For instance, when a stockpile is fed by a stacker or is discharged by a reclaimer [4], see Figure 2 and 3.

Fig. 2 Stockpile discharged by using a Krupp bridge reclaimer at RTCA Kestrel Mine

Another crucial challenge for stockpile measurement is to measure the mixing behaviour of different materials charged to the stockpile. The attributes of mixing behaviour include when and how the mixing takes place in the stockpile and when the mixed materials with certain portion are discharged out of the stockpile.

![Coal stockpile fed by using a Krupp stacker featuring tripper conveyor and non-slewing at RTCA Kestrel Mine](image)

There are some technologies available, used to determine the different materials in a stockpile. Darrell [5] reported the installation of an online analysis at Mitsubishi cement plant, California, USA. The analyser generates neutrons from a radio isotope and then uses the neutrons to interrogate materials and interact with the nuclei of the materials. In doing so, gamma rays are emitted. Each generated gamma ray comes from the nucleus of an element such as calcium (Ca), silicon (Si) or aluminium (Al), and has a unique energy associated with the element from which it was generated. The gamma rays are counted and their energies sorted by a detection mechanism. A spectrum of energies is created and is analysed by software algorithms and gives the concentrations of the different elements. The online analyser generates an analysis of the full material stream in transit to the pre-blending stockpile once per minute, which allows 100% of the raw materials to be analysed while in continuous motion on a conveyor belt.

Geoscan by Scantech, is another online analyser for a wide range of bulk materials, used in mining, coal and cement sectors [6]. The Geoscan analyser uses the technique of prompt gamma neutron activation analysis to perform a minute-by-minute elemental analysis of bulk material passing through it on a standard convey belt. The online analyser can be installed with convey belt sizes from 600 to 2020 mm with unlimited flow rate of material. The lump size of material has no influence on the results. It can measure many element contents, such as Ca, Si, Al, Fe, K, Na, Ti, Mn, S, Cl, Mg, P, moisture, and ash. With the advancement and the wide usage of measurement instruments associated with stockpiles, a smart sensor can be developed to monitor the level of a stockpile. Furthermore the stockpile smart sensor can be used to estimate the mixing behaviour of different materials charged in the stockpile. The mixing behaviour of different materials includes when and how the mixing takes place, and more important, when the mixed materials with a certain blended portion is discharged out of the stockpile.

Furthermore the stockpile smart sensor can be used to estimate the mixing behaviour of different materials charged in the stockpile. The mixing behaviour of different materials includes when and how the mixing takes place, and more important, when the mixed materials with a certain blended portion is discharged out of the stockpile.

II. DEVELOPMENT OF STOCKPILE LEVEL SMART SENSOR

Smart sensor, or soft sensor, is an online software solution. It calculates or estimates the values of unmeasured variables in real time, using the values of online-measured variables. Some of the unmeasured variables are so important but cannot be measured because the measurement technology is not ready yet or because the cost is high to do so. In the last decade, wider usage of measurement instruments has been seen and at the time a greater integration of various process control systems has taken place in the industries of mining, mineral processing and cement. Using the available measurements, various smart sensors have been developed for mining and mineral processing applications in recent years, including weightometer smart sensor [7], densitometer smart sensor [8], ore type smart sensor [9], particle size smart sensor [10].

Other techniques also are made available to help estimate the mixing behaviours of material in and out of the stockpile, including various modelling and simulation tools. For instance, a stockpile optimization software by Actek can estimate stockpile volume, provides optimal reclaim positions for various stockpile types, including circular, linear telescoping and radial stockpiles [11], see in Figure 5.

A typical stockpile consists of a feeding conveyor, a cone space to pile material and discharging hopper and conveyor feeder at the bottom. A stockpile level can be presented by the percentage of fullness in two formats, namely by percentage of mass and by percentage of the level. The mass percentage is defined as the actual mass over the total ore mass of a full stockpile (Mass%). The level percentage is...
the actual height of ore over the maximum height of a full stockpile (Level%). The definition for both Mass% and Level% can be expressed in the following equations:

\[
\text{Mass-full} \% = \frac{(O_t)(O_t-FS)}{O_{t-FS}} \cdot 100
\]
\[
\text{Level-full} \% = \frac{(O_l)(O_l-FS)}{O_{l-FS}} \cdot 100
\]

Where
- \(O_t\) ---- actual ore tonnage in stockpile, ton
- \(O_{t-FS}\) ---- ore tonnage of full stockpile, ton,
- \(O_l\) ---- actual ore level in stockpile, meter,
- \(O_{l-FS}\) ---- ore level of full stockpile, meter.

Consequently the capacity of a stockpile includes ‘live’ and ‘dead’ volumes.

When Mass% is 75% it means the stockpile in tonnage is at 75% full. If the Level% is 75%, then it means the stockpile level is at 75% of the maximum height. The values of Mass% are smoother than the values of Level% in terms of rate of change in real time. Due to the shape of stockpile, the volume is smaller at the top than the volume at the bottom. Consequently the values of Level% will change faster when the stockpile is filled up, even the values of Mass% is still kept at constant level.

It is important to understand the difference between the values of Mass% and Level%, from the view point of operators and process control. When the stockpile level is used to control the feeders, Mass% would be a preferable one, rather than Level%. Interestingly almost all stockpile levels are measured so far in the format of Level% by various measurement technologies, including Yo-Yo (or weight and cable), ultrasonic, laser and radar. As a result, some conversion of Level% to Mass% is required for the purpose of better process control.

It is worthy knowing that the Mass% and Level% measurements need some attention when using them for process control, due to the factor of so-called “dead band”. A dead band is formed at the bottom around the outside of the stockpile, where the ore stays because it stops falling down to the discharging hopper located at the bottom of stockpile, as indicated in the grey area in Figure 6.

Fig. 6 Illustration of a “dead band” formed at the bottom where ore cannot be discharged from a stockpile without being pushed toward the centre

The ore in the dead band may reach 75% of the total ore mass of a full stockpile. Therefore when the stockpile can not discharge any ore, the value of Mass% could be as high as 75%. To discharge the ore in the dead band, extra efforts are required, such as pushing the ore towards the centre so the ore can fall into the feed hopper. Ore fallen in the dead band becomes “dead”. Ore that does not fall in the dead band can be discharged and it is “live”. For the purpose of process control, the ore in the dead band should be taken into account and the value of Mass% should be 0% when no more ore can be discharged from the stockpile even the dead bank is full with ore. The Mass% can be altered to an effective mass% (EMass%) by equation (3):

\[
EMass\% = \frac{(AO_{t})(AO_{t-FS})}{100}
\]

Where
- \(AO_t\) — active ore tonnage in stockpile, ton
- \(AO_{t-FS}\) — active ore tonnage of full stockpile, ton, equalling to the tonnage of ore in a full stockpile subtracted with the ore in dead band.

Stockpile smart sensor can calculate the values of EMass% in real time, using values of 2 weightometers. One weightometer measures the feeding rate of ore and another measures the discharging rate of ore at the associated stockpile. The algorithms used to calculate the effective mass percentage, EMass%, can be described in the following equations when time changes from \(t_0\) to \(t\) seconds:

\[
EMass\%_t = A + B \cdot (dt)
\]

Where
- \(A = EMass\%_0\), \((EMass\%\text{ at time } t_0)\)
- \(B = \frac{d(EMass\%)}{dt} = \frac{(EMass\%_t - EMass\%_0)}{dt}\)
- \(dt = (t - t_0)\)

When \(dt\) is kept at a constant sampling rate of 1 second, then

\[
EMass\%_t = EMass\%_0 + B
\]

\[
B = \frac{[(ore-ton)_t - (ore-ton)_0]}{M}
\]
EMass\%_t and EMass\%_t0 is the value of EMass\% at time \( t \) and time \( t0 \), respectively, 
\( W1_t \) and \( W1_t0 \) is the ore feedrate (ton/hour) of feeding weightometers at time \( t \) and time \( t0 \),
\( W2_t – W2_t0 \) is the ore feedrate (ton/hour) of discharging weightometer at time \( t \) and time \( t0 \),
\( W \) is the total ore tonnage of a full stockpile.

The value of EMass\%_t can be assigned whenever the smart sensor is initiated first time and it can be re-set when the value is known. For instance, EMass\%_t0 = 0%, when the stockpile is empty, and EMass\%_t0 = 100%, when the stockpile is full. The value of the total ore tonnage of a full stockpile, \( M \) can be obtained from the design document of the stockpile, or it can be calculated from the following equation, see in figure 7:

\[
M \text{ (in ton)} = V_a \times \rho \\
V_a = \frac{1}{3} \times \pi \times R^2 \times (H_0 - H_1) + \frac{1}{3} \times \pi \times H_1 \times (R^2_1 + R^2_2 + R_1 \times R_2) \\
R_0 = \frac{D}{2} \\
R_1 = \frac{D_1}{2} \\
R_2 = \frac{D_2}{2}
\]  

Where

- \( M \) ---- tonnage of ore in a stockpile,
- \( \rho \) ---- density of bulk ore,
- \( V_a \) ---- live volume of stockpile(excepted the volume of dead band),
- \( D \) ---- diameter,
- \( R \) ---- radius,
- \( H \) ---- height of the stockpile,
- \( H_1 \) ---- height of dead band.

The diameter and the height of the stockpile \( D \) and \( H \) are at constant values, and the diameter and height of actual ore in the stockpile, \( d \) and \( h \), are not constant, and they are changing with time.

Therefore, based on the real time measurements of 2 weightometers \( (W_1 \) and \( W_2) \), the effective mass percentage in a stockpile can be estimated with the ore tonnage \( (EMass\%) \), existing in the live capacity of a stockpile at any time. The accuracy of the mass percentage is dependent on the accuracy of the weightometers mentioned above. Those weightometers, measured the feed rate and discharged rate for a stockpile, are normally regarded as critical weightometers at the mine, because their values are used to indicate the production over a period of time, such as a day, a month, which are linked to the key performance indicators (KPIs). In most cases, an extra weightometer is installed in redundancy to each of those weightometers. A cost effective way is to implement weightometer smart sensors for those critical weightometers, as mentioned in those detailed reports [7, 8, 9].

Based on the indication of the effective mass percentage in a stockpile, the mixing behaviour of the ore can be estimated as well, using the result of discrete element modelling [9], see in Figure 8, 9.

The stockpile smart sensor can help estimate accurate residual time for different group of ores charged to the stockpile. The smart sensor makes it possible to monitor the behaviour of different ore types in real time in a stockpile, including when and how the different ores are mixed in the stockpile and when the mixed ores are discharged with certain mixing portion. Using the smart sensor system, the information on the ore types can be provided for ores that are discharged from the stockpile.

The ore type information includes ore grade, density, hardness, strength, etc. The results can be seen in Figure 10 for the stockpile levels and ores types, being fed in and discharged at four stockpiles (main stockpile, coarse stockpile, fine stockpile, re-crush stockpile). Those results are displayed in a SCADA system of a diamond mine where...
the stockpile smart sensors and ore type smart sensors are implemented [9].

III. DISCUSSION

A. Stockpile Level Measurement

Many different technologies are available today to measure stockpile levels, and it is important to know that no one is suitable for all applications [1]. Therefore it is imperative to understand fully the required process needs and the capabilities of various level measurement technologies, before deciding on a level measurement solution for a solid stockpile.

1) Plumb Bob

This technique uses an automated mechanical rope and is referred to by numerous names, including a Yo-Yo (a registered trademark of Bindicator), plumb-bob, and weight and cable [2]. A weight is suspended by a cable from a drum operated by a motor, see in Figure 11, and the motor unwinds the cable until the weight reaches the material surface. The length of the unwound cable is the measured distance to the material, calculated using electrical pulses from an encoder assembly. The advantage of this technology is that it is reasonably accurate, easy to install and low cost. Its disadvantages include mechanical wearing on parts, resulting in high maintenance costs and the damage to the weight and/or cable during the filling of the stockpiles because the weight can become stuck under failing material, particularly when the material poses a high density or big size, such as various ores of mineral processing.

![Image](image.png)

**Fig. 10 Display of levels and information of ore types at various stockpiles at a diamond mine, including indications of ore grade, ore density, and percentage of mixed ores by various pie-charts**

Ultrasonic technology uses high frequency sound waves directed to the material by a transducer and measures the time-of-light to and from the material in the stockpile, see in Figure 12. It offers a very cost effective high performance solution for these applications given the following characteristics:

- Measurement ranges are usually short, less than 10 m
- Dust levels are not severe
- High shock and high vibration
- Unrestricted use in “open air” environments
- Material with low dielectric
- Material with high density

![Image](image.png)

**Fig. 11 Stockpile level measured by a plumb Bob, or so-called Yo-Yo device**

2) Ultrasonic Technology

The main advantages of ultrasonic technology are that it is low cost, non-contacting and highly reliable. Ranges of up to 60 m are typically promoted. However, this maximum range quickly deteriorates with the intensity of dust on the stockpiles. Since ultrasonic technology required a carrier
medium (normally air), any change to this medium has an
effect on the measurement. High temperature of the materials
in the stockpile also changes the speed of transmission and
leads to accuracy problems. Other factors also create accuracy
problems for the level measurement, such as material
echoing, sloped surfaces of the material.

3) Radar Technology

Radar (Radio Detection And Ranging) technology has been
used successfully for liquid level measurement since the mid
1970s on large storage vessels, but the cost were high (T.
Little, non-contact level measurement in “open air”
applications)[3]. More recently, as the cost decreased and the
technology developed further, radar devices have gained
wide acceptence and have achieved high growth rates on
solid level applications, such as stockpiles in
mining/mineral processing and cement industry. It uses
electromagnetic waves in the microwave spectrum between
1 and 300 GHz, which travel at the speed of light and are
virtually unaffected by the environment it travels through, such as
vapour, pressure, temperature, and dust. Radar works well
in solid stockpiles where other technologies cannot
handle, such as the stockpiles of cement industry due to the
existence of intensive dust. In fact radar has become the
preferred level measurement technology today in the
cement industry for long range dusty applications.

Fig.12. Stockpile level Measured by an Ultrasonic Device

IV. CONCLUSIONS

Knowing the material or ore level in a stockpile is
extremely important in the industries of
mining, mineral
processing and cement. Depending on the users, some are
satisfied with approximations while others require specific
and very accurate knowledge of the material in a stockpile,
including levels and mixing behaviour. Accuracy challenges
are presented mainly by the types and sizes of a stockpile and the
ore types in the stockpile. Various technologies are available to
provide the level measurements for a stockpile, including Yo-
Yo or weight and cable, laser and radar. It is important for
users to understand the required measurement task and the
process need before deciding on a level measurement solution.
Safety and reliability, and accuracy remain crucial, while at
the same time, the specific measurement equipment needs to
be chosen with the consideration of easy to install and
operate at a low cost of ownership. A software based level
measurement, level smart sensor, proves an attractive
alternative.

With the advancement and the wide usage of measurement
instruments associated with stockpiles, a smart sensor can be
developed to monitor the level of a stockpile. The smart sensor
makes it possible to monitor the behaviour of different ore
types in real time, including when and how the different ores
are mixed in the stockpile and when the mixed ores are
discharged with certain mixing portion.
